Clone stability and in vitro phytoextraction capacity of vegetative clones of P. x canescens (2n = 4x = 38) including two transgenic clones (ggs11 and lgl6) were studied as in vitro leaf disc cultures. Presence of the gshI-transgene in the transformed clones was detected in PCR reactions using gshI-specific primers. Clone stability was determined by fAFLP (fluorescent amplified DNA fragment length polymorphism) analysis. In total, 682 AFLP fragments were identified generated by twelve selective primer pairs after EcoRI–MseI digestion. Four fragments generated by EcoAGT–MseCCC were different (99.4% genetic similarity) which proves an unexpectedly low bud mutation frequency in P. x canescens. For the study of phytoextraction capacity leaf discs (8 mm) were exposed to a concentration series of ZnSO4 (10⁻¹ to 10⁻⁵ M) incubated for 21 days on aseptic tissue culture media WPM containing 1 µM Cu. Zn²⁺ caused phytotoxicity only at high concentrations (10⁻¹ to 10⁻² M). The transgenic poplar cyt-ECS (ggs11) clone, as stimulated by the presence of Zn, showed elevated heavy metal (Cu) uptake as compared to the non-transformed clone. These results suggest that gshI-transgenic poplars may be suitable for phytoremediation of soils contaminated with zinc and copper.

Key words: Phytoextraction, cyt-ECS (ggs11), chl-ECS (lgl6)

Introduction

Poplars (Populus ssp.) are known to take up and detoxify pollutants from the soil, such as atrazine and chloroacetanilide herbicides, organic pollutants such as trinitrotoluene and trichloroethylene, as well as heavy metals such as mercury and selenium (Gullner et al., 2001). This remediative capacity of poplars may be significantly increased by cell and genetic manipulations. P. x canescens was transformed recently to overexpress the bacterial gene encoding γ-glutamylcysteine synthetase (γ-ECS, EC 3.2.3.3) which is the rate-limiting regulatory enzyme in the biosynthesis of the ubiquitous tripeptide thiol compound glutathione (GSH, γ-L-glutamyl-L-cysteinyl-glycine) which plays a central role in plant detoxification processes (Kömives and Gullner, 2000; Schröder et al., 2001). In the present study phytoextraction activity was investigated in the wild-type poplar hybrid P. x canescens (P. tremula × P. alba) and two transgenic lines overexpressing γ-ECS either in the cytosol (line ggs11 of Arisi et al., 1997) or in the chloroplasts (line lgl6 of Noctor et al., 1998) following a 21 day exposure to ZnSO₄ (10⁻¹ to 10⁻⁵ M) in vitro. Prior to the experiments genetic stability of the poplar cut clones was determined by AFLP analysis. The presence of the gshI-transgene was detected using gshI-specific primers.

Materials and Methods

Plant material

Clones of the untransformed INRA 717–1-B4 hybrid poplar P. x canescens (P. tremula × P. alba) and two genetically transformed lines overexpress-
ing the gshI (Escherichia coli) gene product of glutathione (GSH) in the cytosol: line ggs11 (Arisi et al., 1997) and in the chloroplasts: line lg6, also designated as Lggs (Noctor et al., 1998) were micropropagated and maintained in aseptic shoot culture in vitro (Kiss et al., 2001; Koprivova et al., 2002).

**Shoot culture**

Poplar clones were micropropagated by nodal segments using a two step protocol. First, shoot segments (0.5 cm) were laid onto WPM media (Lloyd and McCown, 1980) supplemented with benzyl adenine (BA, 0.5 mg/l) and naphthalene acetic acid (NAA, 0.2 mg/l) followed by incubation for 28 d in a 16 h/8 h light/dark (1000 lx) photoperiod. Auxiliary shoots developed were dissected and transferred onto hormone-free WPM segments using a two step protocol. First, shoot segments (0.5 cm) were laid onto WPM media supplemented with acetic acid (NAA, 0.2 mg/l) followed by incubation for 28 d in a 16 h/8 h light/dark (1000 lx) photoperiod. Auxiliary shoots developed were dissected and transferred onto hormone-free WPM (Lloyd and McCown, 1980) media and incubated for additional 28 d for rooting according to Kiss et al. (1995). Leaves of rooted shoots were used for leaf disc cultures according to Gyulai et al. (1997).

**DNA extraction**

Total DNA samples of 0.1 g leaf tissue in each case were extracted in CTAB (cetyltrimethylammonium bromide) buffer (Murray and Thompson, 1980; Doyle and Doyle, 1990) followed by RNase-A (from bovine pancreas) treatment (Sigma, R-4875), for 30 min at 37 °C. DNA samples of ten individual of each line were pooled in one bulk according to Michelmore et al. (1991). The undiluted genomic DNA samples were subjected to PCR and AFLP analysis.

**PCR**

Hot Start PCR (Erlich et al., 1991) was combined with Touchdown PCR (Don et al., 1991) using AmpliTaq Gold™ Polymerase. The reactions were carried out in a total volume of 10 μl (AFLP) and 25 μl (transgene detection), respectively, containing genomic DNA of 50 ng. For transgene analysis 1 × PCR buffer (2.5 mM MgCl₂), dNTPs (200 μM each), 20 pmol of each primer and 0.5 U of Taq polymerase was used (Heinz, 1998). Touchdown PCR was performed by decreasing the annealing temperature from 66 °C to 56 °C by 0.7 °C/30 s increments per cycle with each of the initial 12 cycles (PE 9700, Applied Biosystems), followed by a ‘touchdown’ annealing temperature for the remaining 25 cycles at 56 °C for 30 s with a final cycle of 60 °C for 45 min (AFLP) or 72 °C for 10 min (transgene detection) and a hold at 4 °C. A minimum of three independent DNA preparations of each sample was used. Amplifications were assayed prior to AFLP analysis by agarose (1.8 %, SeaKem LE, FMC) gel electrophoresis (Owl system), stained with ethidium bromide (0.5 ng/μl) after running at 80 V in 1 x TAE buffer. Each successful reaction with scorable bands was repeated at least twice. Transilluminated gels were analyzed by the ChemiImager v 5.5 computer program (Alpha Innotech Corporation – Bio-Science Kft, Budapest, Hungary). A negative control which contained all the necessary PCR components except template DNA was included in the PCR runs.

**AFLP analysis**

Bulked DNA samples of ten individual shoots of each line (wild-type, cyt-ECS and chl-ECS) were pooled (5.5 μl) and subjected to fAFLP (fluorescent amplified DNA fragment length polymorphism) analysis following the method of Vos et al. (1995) with modifications (Cresswell et al., 2001; Skot et al., 2002). For digestion-ligation reactions, pairs of EcoRI–MseI restriction endonucleases (REases) were used (Table I). The sequences of the preselective primers were: EcoA: gac tgc gta cca attc-a, and MseC: gat gag tca tga gtaa-c. For selective amplification 24 primer combinations were used with JOE (green) fluorescent labeled *Eco*-primers. In primer combinations 1 to 12 the primer Mse-CAC was combined with labeled primers of *Eco* -aaa, -aac, -aag, -aat, -aca, -acc, -agg, -act, -aga, -agc, -agg, -agt. In primer combinations 13 to 24 the labeled primer *Eco*-AGT was combined with primers of Mse -caa, -cag, -cat, -cca, -ccc, -ccg, -cct, -cga, -cgc, -cgg, -cgt, -cta. All oligonucleotides were supplied by Sigma Genosys and enzymes by Roche Diagnostics. Digestion of DNA, adapter ligation, non-selective and selective amplifications are described in detail by Cresswell et al. (2001) and the sequences of adapters and primers used are listed (Table I). PCR-amplified AFLP fragments were subsequently denatured at 98 °C for 5 min, and kept at 60 °C for 30 min to allow DNA heteroduplex formation, or directly forwarded to an ABI PRISM 3100 Genetic Analyzer (Applied Biosystems) using a G5 filter set in two repetitions, and analyzed by ABI PRISM Genotyper 3.7 NT software.

Transgene detection

The gsh1-transgene (E. coli, NCBI No. X03954) in the transformed poplar clones was amplified by the gsh1-specific primer 5’-atccggacgtacatcagga-3’ (position bp 341–359 in gsh1) and its reverse 3’-gatgcaccaaacagataagg-5’ (position bp 939–920 in gsh1) according to Koprivova et al. (2002). Amplification reactions were run at a volume of 25 µl containing 50 ng DNA by a PE-9700 thermocycler.

Phytoextraction

Leaves were taken from the aseptic shoot cultures and discs (8 mm) were cut and placed onto the surface of tissue culture media WPM (Lloyd and McCown, 1980) with supplementation of a concentration series of ZnSO₄ (10⁻¹ to 10⁻⁵ M) followed by incubation for 21 d according to Gyulai et al. (1995). Eight leaf discs per Petri dish (10 cm) were applied at each concentration in three repetitions. Zn-free WPM basal medium contained 63.6 µg (1.0 µM) Cu applied as CuSO₄ ⋅ 7H₂O (Mᵣ 287.4).

ICP analysis

After 21 d exposure of discs heavy metal contents (Zn and Cu) mean values of three independent measurements were determined by inductively coupled plasma emission spectrometry (Zarcinas et al., 1987).

Statistics

At least three independent parallel experiments were carried out in each case. Differences between mean values were evaluated by Student’s t-test at P = 0.05.

Results and Discussion

The in situ application of transgenic plants for phytoremediation purposes needs an in vitro vegetative multiplication period with the possibility of transgene elimination as a result of bud mutation or gene segregation. Transgenic poplar clones used in the present study were micropropagated in aseptic in vitro shoot culture by nodal segments for several years (Arisi et al., 1997; Noctor et al.,
1998) which prompted a study of the genetic stability.

The gsh1-poplar (P. × canescens) was developed to overexpress the bacterial gene encoding γ-glutamylcysteine synthetase (γ-ECS, EC 3.2.3.3) which is the rate-limiting regulatory enzyme in the biosynthesis of GSH (γ-L-glutamyl-L-cysteinyl-glycine) (Arisi et al., 1997; Noctor et al., 1998). The increased production of GSH contributes to the antioxidative protection of plant cells against oxidative stress (Böger and Wakabayashi, 1995) caused by various environmental pollutants such as heavy metals, herbicides, fungicides (Kömives and Gullner, 2000; Koprivova et al., 2002).

gsh1-transgene stability

Double strand breaks (DSBs) of DNA as the initial events of recombination occur not only in the meiotic cells but also in the somatic cells (Puchta, 1999; Frewen et al., 2000; Rohde et al., 2002) which can cause a transgene distortion. In our experiments, the gsh1-transgene was found to be stable in all the tested poplar clones (ggs11 and lgl6) indicating no transgene elimination or segregation (Fig. 1).

AFLP analysis

Cut clone stability was analyzed by fAFLP. Twelve of the 24 selective primer combinations applied were effective in producing sharp and reproducible AFLP patterns (Fig. 2). A total of 682 common AFLP fragments were detected (Table II). The average number of ALF fragments per selective primer pair was 56.6 which falls in the same range as was observed in an analysis of black poplar (P. nigra) clones with a total of 104 AFLP fragments generated by two primer pairs (Smulders et al., 2002). The most effective primer pair was found to be the EcoAGT-MseCAT resulting in 35 AFLP fragments (Table II). In a comparative preliminary study with wheat (Triticum aestivum L.) the EcoAGT-MseCAC produced the most ALF fragments (47).

These results appear to reflect some relationship between AFLP fragment number and genome size. The genome size of wheat (Triticum aestivum) is very large (2n = 6x = 42; 16 × 10⁹ bp, which is equal to 16.58 pg as calculated by the equation 965 Mbp = 1 pg DNA) compared with the extremely small genome size of poplar (2n = 4x = 38; 5.5 × 10⁸ bp; 2C = 1.1 pg) (Cervera et al., 2001; Taylor, 2002).

Four AFLP fragments were polymorphic of the total 682 fragments (99.4% genetic similarity) which appeared in the untransformed clone and in the gsh1-transgenic lgl6 clone generated by EcoAGT-MseCCC (Table II, Fig. 2). Despite trees with high bud mutation rate (Rohde et al., 2002) such as apple, this result indicates an unexpectedly low level of bud mutation in P. × canescens cut clones thus providing genetically uniform plant material for phytoextraction purposes.

Phytoremediation in vitro

Field trials of transgenic plants are under strict regulation, hence an in vitro analysis for phytoextraction capacity as done in the present study is essential prior to any field test. The heavy metal contents of leaf discs analyzed in the poplar clones following Zn stress (10⁻¹ to 10⁻⁵ m) showed a complex pattern (Table III). The Zn uptake...
increased linearly with the exogenously applied concentrations of ZnSO₄ in all clones. None of the gshI-transgenic clones (ggs11 and lgl6) showed elevated Zn uptake capacity.

An unexpected Zn-stimulated Cu uptake was observed in the transgenic cyt-ECS (ggs11) clone with a peak at 10⁻² M ZnSO₄ concentration (331.6%). An enhanced Cd uptake in the ggs11 poplar clone was also found in ex vitro experiments (Koprivova et al., 2002). With regard to metallothioneins (MTs), metal transporter proteins (MTPs), phytochelatins (PCs) and the precursor of sulphur-rich peptides like glutathione (GSH), no genes conferring metal resistance have been identified in any of the naturally occurring hyper-accumulating species. These species include Thlaspi caerulescens, as a known Ni and Zn hyper-accumulator, and Brassica juncea as a known Pb accumulator (Gleba et al., 1999).

Reactive metal ions such as Cu²⁺ and Zn²⁺ can interfere with sulphhydryl (SH) groups of proteins, therefore should be inactivated in the cell through sequestration by cysteine-rich PCs, MTs and sulphide. The cysteiny sulphur in the peptides and proteins function as ligands for the metal ion as supported by SO₄²⁻ of the zinc form (ZnSO₄) applied in the present study. Ultimately, the metals are bound in polynuclear metal thiolate clusters (Dame-

Doyle J. J. and Doyle J. L. (1990), Isolation of plant DNA from fresh tissue. Focus 12, 13–15.

The capacity to synthesize PCs is supposed to be present in all higher plants. Their synthesis from GSH and different forms of GSHs such as homo-glutathione, hydroxymethyl-glutathione or γ-glutamylcysteine is catalyzed by a constitutive transpeptidase enzyme, the phytochelatin synthase (PCS). PCS requires a post-translational activation by heavy metals, in particular Cd, Ag, Pb, Cu, Hg, Zn, Sn, Au, and As, both in vivo and in vitro (Schat et al., 2002; Grill et al., 1988; Maitani et al., 1996). Nevertheless, a PC-independent sequestration mechanism was also reported in plants (Schat et al., 2002).

Our results confirm that under in vitro conditions the ZnSO₄ stimulated accumulation of Cu in the transgenic ggs11 (cyt-ECS) clone is improved by the gshI-transgene which thus provides potential to develop transgenic phytoextractor poplar for ex vitro purposes.
